Abstract: Software reliability prediction is very challenging in maintenance phase as well as in the starting phases of software development. In the past few years many software reliability models have been proposed for assessing reliability of software but developing accurate reliability prediction models is difficult due to the recurrent or frequent changes in data in the domain of software engineering. As a result, the software reliability prediction models built on one dataset show a significant decrease in their accuracy when they are used with new data. The objective of this paper is to introduce a new approach that optimizes the accuracy of software reliability predictive models when used with raw data. Ant Colony Optimization Technique (ACOT) is proposed to predict software reliability based on data collected from literature. An ant colony system by combining Travelling Sales Problem (TSP) algorithm has been used, which has been changed by implementing different algorithms and extra functionality, in an attempt to achieve better software reliability results with new data for change oriented systems. The intellectual behavior of the ant colony framework by means of a colony of cooperating artificial ants are resulting in very promising results. The method is validated with real dataset using Mean Time to Failure (MTTF) and Mean Time Between Failure (MTBF).

Keywords: Software Reliability, Bio-inspired Computing, Ant Colony Optimization technique.

I. INTRODUCTION

As the past decades have seen the computerization of all the functionalities in all the fields turn out to be supplementary multifaceted and therefore, there is a constant demand for discovering innovative well organized methodologies to software development and preservation. There is a prerequisite of the enormous scope of effort, time and currency to arrange and build up any feasible software apart from the human resource and their organization. For outstanding rising competition, today's profitable conditions have become very dynamic. Corporate industries require proceeding extremely fast to unstable needs of the market. Hence, software engineering which emphasizes with all these regions has become an individual study from researchers. The software crisis is defined as mismatch between what the software can deliver and the capacities of computer systems, as well as the expectations of their users and where software problems cause the system tasks to be delayed, expensive, and/or not amenable to the user’s desires. Apart from software can be developed to meet the various stages of reliability, security, portability, usability, effective cost and response time.

Developing awfully trustworthy software from the user’s perspective is a demanding profession for all software engineers. However, Software Reliability is a significant aspect influencing system reliability. The following four
practical aspects which are related to achieving reliable software systems and these aspects furthermore be treated as four fault Lifecycle techniques:

1) Fault avoidance: to avoid, by building, error existence. 2) Fault elimination: to identify, by confirmation and proof, the presence of faults and eliminate them. 3) Fault tolerance: to specify, by redundancy, facility conforming to the requirement in spite of faults having rising. 4) Fault/failure Predicting to estimate: by the assessment, the occurrence of faults and consequences of failures.

Software reliability is the probability that software will not cause the failure of a system for a particular point in time underneath particular circumstances. The probability is a function of the inputs to and use of the system as well as a function of the existence of faults in the software. According to ANSI, Software Reliability is defined as: “the probability of failure free software operation for a particular period of time in a particular atmosphere”. Software reliability evaluation is significant to evaluate and forecast the trustworthiness and performance of software systems. Reliability representation is a crucial ingredient of the reliability evaluation procedure and it also validate whether a product meets up its reliability objective and is ready to distribute. The fundamental intention of most of software reliability models is making them to understand distinctiveness and reasons to fail software, and try to enumerate software reliability. The current article lay emphasis on about a bio inspired computing technique Swarm Intelligence known as the Ant Colony Optimization Technique to predict software reliability. The anticipated method is employed into a TSP problem with software failure datasets to predict software reliability and the results of our approach are reported. And, thus, the focus of the discussion to be presented here is an ACO for discrete optimization that has been used to predict software reliability using the Travelling Sales Person Problem where failure data is given as input and the result is calculated through Mean Time to Failure (MTTF) and Mean Time Between Failure (MTBF) to predict the reliability.

II. METHODOLOGY

A. Bio Inspired Computing:

Natural computing [22] is a term presented to comprise three classes of methods: (1) those that take motivation from nature for the development of novel problem-solving techniques; (2) those that are constructed with the use of computers to synthesize natural facts; and (3) those that employ natural resources (e.g., molecules) to compute. The main areas of research that comprise these three branches are the artificial neural networks, evolutionary algorithms, swarm intelligence, artificial immune systems, fractal geometry, artificial life, DNA computing, and quantum computing, among others. Bioinspired Computing is the combination of computational aptitude and collective intelligence. These computational approaches are used to resolve multifaceted problems, and developed after design principles confronted in natural / biological systems, and tend to be adaptive, responsive, and distributed. The aim of bio-inspired computing is to develop computational tools with enhanced strength, scalability, flexibility and which can interact more efficiently with humans. It can offer biologists, for example, with an IT-oriented concept for looking at how cells compute or process information, or help computer scientists build algorithms based on natural systems, such as evolutionary and genetic algorithms.

Biocomputing [23] has the potential to be a very powerful tool. The association of bio-inspired computing are artificial neural networks, evolutionary algorithms, swarm intelligence, artificial immune systems, fractal geometry, artificial life, DNA computing and quantum computing.

B. Ant Colony Optimization Technique:

Ant Colony [24-27] is one of the techniques of bio inspired computing. The main concept of this is technique is that the self-organizing rules which allow the highly synchronized behavior of real ants can be utilized to manage populations of artificial agents that cooperate to solve computational problems. Various distinctive attributes of the behavior of ant colonies have inspired different kinds of ant algorithms. Examples are foraging, distribution of labor, issue sorting, and cooperative transport. Ants coordinate their activities via stigmergy, a form of implicit interaction mediated by changes in the environment. For example, a foraging ant deposit a chemical on the ground which raises the probability that other ant will follow the same path. Biologists have presented that many colony-level behaviors witnessed in social insects can be described through relatively simple models in which only stigmergic communication is present. In other words, biologists
Novelty Journals have shown that it is often sufficient to consider stigmergic, indirect communication to explain how social insects can attain self-organization. The notion behind ant algorithms is to use a form of artificial stigmergy to coordinate societies of artificial agents. One of the most effective examples of ant algorithms is known as “ant colony optimization”, or ACO. ACO is motivated by the foraging behavior of ant colonies, and targets discrete optimization problems. The ants may deposit a pheromone on the ground while returning back to their nests. The ants follow with high probability pheromone trails their sense on the ground.

Each Ant evaluates the next move to another vertex based on Gambardella et al., [28, 29],

- Mean Time to Failure (MTTF)
  - MTBF = Mean Time Between Failure
  - MTTR = Mean Time to Repair
- Reliability = MTBF / (1+MTBF)

**Mean Time to Failure:**

- Measures time between observable system failures

For example, assume you tested 3 identical systems starting from time 0 until all of them failed. The first system failed at 10 hours, the second failed at 12 hours and the third failed at 13 hours. The MTTF is the average of the three failure times, which is 11.6667 hours.

If these three failures are random samples from a population and the failure times of this population follow a distribution with a probability density function (pdf) \( f(t) \), then the population MTTF can be mathematically calculated by:

\[
\text{MTTF} = \int_0^\infty tf(t)dt = \int_0^\infty R(t)dt
\]

If all the uptime durations \( x \) are independent and identically distributed (i.i.d) and all the repair durations \( y \) are i.i.d, then:

\[
\text{MTBDE} = \text{MTBF} + \text{MTTR} \quad \text{(Mean Time to Repair)}
\]

**Mean Time Between Failure:**

The points on the plot are the observed cumulative MTBFs. These values are calculated by the following equation:

\[
\text{MTBF}(t) = \frac{t}{N(t)}
\]

where:

- \( t \) is the cumulative operating time.
- \( N(t) \) is the observed number of failures by time \( t \).

**Algorithm:**

The ACO algorithm [30] which has been proposed based on the study that real ants are skilled in finding the shortest path from a food source to the nest without using visual signals. From the originating point the ants start the tour selecting randomly any path.

1. **Set the initial parameters.**
2. **Initialize pheromone trails.**
3. **Calculate the maximum specific ways in which the ants can travel.**
4. **Loop //iteration**
5. Each ant is positioned at a given node randomly selecting the node according to some distribution strategy (each node has at least one ant)

6. For k=1 to m do //steps in a loop

7. The first step: move each ant in a different route

8. Repeat //till all the nodes are visited

9. Select node j to be visited next // the next node must not be an already visited node

10. Apply local updating rule

11. Until ant k has completed a tour

12. End for

13. Apply sub tour that is sub Local search // to improve tour

14. Apply global updating rule

15. Compute entropy value of current pheromone trails

16. Update the heuristic parameter

17. Until End_condition

18. End

The flow chart of the ACO algorithm is presented in Fig. 1.
III. CONCLUSIONS

In this paper, ACOT using software reliability datasets can be employed. The performance of ACOT that of BPNN, TANN, PSN, MARS, GRNN, MLR, TreeNet, DENFIS, Morlet based WNN and Gaussian based WNN can be compared. It is observed that the performance of ACOT is better when compared with other techniques when combined with error checking computational method.

Thus, ACOT holds a very good promise in the field of software reliability.
